ABSTRACT:
Introduction: Hypertension is the most common cardiovascular disorder, affecting 20 % of the adult population world wide. It is linked with coronary heart disease, stroke, congestive cardiac failure and renal dysfunction and is one of the major risk factor for cardiovascular mortality, which accounts for 20 to 50 % of all deaths. The use of calcium channel blocking agents in the treatment of hypertension shows the critical importance of calcium in the biochemical control of vascular smooth muscle tone, and thus of blood pressure homeostasis. Material and Methods: This study was conducted at D.B. government hospital churu at department of medicine OPD; we enroll 50 healthy and 50 hypertensive patients, those were fulfilling the inclusion criteria of study. A complete medical history of these subjects was first obtained which provide the basis for selection. Result: Our study showed a significant high levels of serum calcium were found in hypertensive group as compared to normotensive group (P <0.01). A statistically significant linear correlation was found between serum calcium and both systolic and diastolic blood pressure in hypertensive males (P<0.01). Conclusion: Our study shows a significant correlation between high serum calcium levels and high blood pressure. Hence, serum calcium levels should be estimated in hypertensive patients.

Key words: Hypertension, coronary heart disease, serum calcium.

INTRODUCTION:
The significance of calcium in cardiac muscle contraction has been more and more recognized. The use of calcium channel blocking agents in the treatment of hypertension shows the significant importance of calcium in the biochemical control of vascular smooth muscle tone, and thus of blood pressure homeostasis. Even with the advances, the relation of clinical aspects of calcium metabolism such as dietary calcium intake, renal disposition of calcium and circulating levels of calcium regulating hormones, as well as calcium itself, to disorders of blood pressure regulation such as hypertension remains an ambiguous one. A speedily expanding literature suggest that alterations of these clinical metabolic variables are indeed found in human hypertensive disease and they may contribute to the pathophysiology of hypertension. However, these alteration seem to advocate that calcium may either exacerbate or alleviate hypertension.
in concomitant elevation or suppression of blood pressure\textsuperscript{12,13} and the chronic hypercalcemia of hyperparathyroidism and vitamin D intoxication is also associated with an increased incidence of chronic hypertension\textsuperscript{14}. These all studies tend to portray calcium as a pathogenic or exacerbating factor in hypertensive disease.

**MATERIAL AND METHODS:**
The subjects incorporated in our study were 50 hypertensive patients, who attended medicine opd of Churu Hospital for minor ailments other than hypertension. Healthy age, sex and diet matched 50 normotensive individuals served as controls. All the individuals selected were in fact in good general health. A full medical history of these subjects was first obtained which provided the basis for selection.

**Inclusion Criteria:** All the male subjects belonged to the age group 22 – 75 years. All the subjects had their weight between 52 -92 kgs .Only subjects with mixed diet were included in the study. Subjects who did not give history of consuming alcohol and smoking were taken.

**Exclusion Criteria:** Subjects with clinical history of ischemic heart disease, thyroid, hepatic, renal or pancreatic disorders. Subjects who were on any drugs for systemic disease.

**Method:**
Measurement of arterial blood pressure: It was based on actual blood pressure recorded with standard mercury sphygmanometer. Blood pressure was recorded from the right arm for three times at three minute intervals with the subject in supine position.

Estimation of serum calcium level: Serum calcium estimation was done by Trinder’s method. With the help of photometric technique\textsuperscript{15,16}.

**Statistical Analysis:**
To test whether there was any significant difference in the study variables between the study groups (normotensives and hypertensives ), Z test was applied. The Z test is a test of significance between mean values of any two groups whose number is more than 30.

**RESULTS:**
Table 1 indicate that out of 50 normotensive patients studied their age were between 22-75 yrs, while the hypertensive patients had their age between 25-73 years .The mean age of normotensive patients was 44.14 years and the standard deviation worked out to be 13.3057 years. The mean age of hypertensive was 42.54 years with a standard deviation of 10.2649.

Mean serum calcium of the normotensive group was 9.268mgm% with a standard deviation of 0.6460 and standard error of 0.0913. Mean serum calcium of the hypertensive group was 11.232 with a standard deviation of 1.1875 and standard error of 0.1679. There is an apparent difference in the two observed means .Z test was applied to test this difference .The Z value worked out to be 4.2786,which was statistically significant i.e P<0.01. Thus it is highly unlikely that this difference has occurred by chance. Thus, findings were confirmed by the 95% confidence intervals values in the two groups .In the normotensive group the 95% confidence interval limits were 9.08-9.45. 95% confidence intervals limits in the hypertension group were 10.9-11.56. As the above limits in the two groups do not overlap ,there is a significant difference between mean serum calcium values in the normotensive group viz hypertensive group. (table 2)

In all the four situations, the correlation coefficient were highly significant at degrees of freedom, 48(n-2) (P<0.01).Thus, correlation between the above variables is highly unlikely to have occurred by chance and is highly significant. (Table 3)

DISCUSSION:
We know that Cardiac muscle relaxes completely between beats. Under these situation, calcium is well below 10^-7 M, the threshold concentration for contraction. A different situation is encountered in vascular smooth muscle. Some resting tension (tone) is normally maintained in most resistance vessels. This imply that intracellular calcium, must be constantly maintained above 10^-7 M because there is no reason to believe that other factors such as the intracellular magnesium or adenosine 5 triphosphate concentrations are limiting. It is generally recognized that most forms of hypertension are associated with an increased peripheral resistance due to maintained abnormal constriction of the small “resistance vessels”. Thickening of the vessel walls and consequent narrowing of lumina may contribute to the maintenance of chronic hypertensive state. In our study, a significant high levels of serum calcium were found in hypertensive group as compared to normotensive group (P<0.01). Tobain L. J. has stressed the fact that increased vascular smooth muscle tone must play an important role. Hypertension is usually present before the vessel wall changes occur and the blood pressure can return to normal after treatment, even though the vessel walls throughout the body remained thickened. Thus, changes in tone reflect changes in intracellular calcium and that a rise in the mean intracellular calcium may be final common path by which most, if not all, hypertension is produced. Several lines of evidence support that the level of serum calcium may play a role in the regulation of blood pressure. Theoretically, such an effect may be mediated through a primary change in cardiac output or peripheral vascular resistance or both, or through altered release or action, or both, of presser substances such as renin and catecholamines.
Shiner P. T et al. reported, increased myocardial contractility and bradycardia without significant change in blood pressure during a short infusion in unanaesthetized dogs. Studies using local perfusion of the forelimb, kidney or heart in the dog showed that a slight elevation of calcium in the perfusate caused both arteriolar constriction and increased myocardial contractility. But no consistent change in cardiac output or peripheral vascular resistance or both, or through altered release or action, or both, of presser substances such as renin and catecholamines.
In the present study, the total serum calcium level is studied. The ionized serum calcium level is not studied. It can be assumed however, that in a population with a normal total serum protein content and a normal serum pH both factors known to influence the relation between total serum calcium – ionised calcium will be a constant function of total serum calcium. Our findings might also help to explain the beneficial role of calcium antagonists in the treatment of hypertension. It is quite clear from this study that increased serum calcium level is significantly associated with hypertension and so by giving calcium supplement it might worsen the situation. Hence, its use in the treatment of hypertensive patients is questionable and needed to be studied in great detail. Though some studies contradict this statement.

CONCLUSION:
Our study shows a significant correlation between high serum calcium levels and high blood pressure. According to the present study, increased serum calcium leads to hypertension. Hence, serum calcium levels should be estimated in hypertensive patients.
